27 **Abstract**

28 **Purpose:** To report the clinical course and high resolution images with autosomal recessive retinitis
29 pigmentosa (RP) associated with a variant of the *RPL* gene (c.4052_4053ins328/p.Tyr1352Alafs*9;
30 m1). This variant has been found to be a high frequency founder variant in Japanese RP patients.

31 **Study Design:** Retrospective case series

32 **Methods:** Nine patients from 5 unrelated Japanese families were studied. Five patients had the m1
33 variant homozygously, and 4 patients had the m1 variant compound heterozygously with another
34 frameshift variant, (c.4196delG/p.Cys1399Leufs*5). Ophthalmic examinations including adaptive
35 optics (AO) fundus imaging were performed periodically.

36 **Results:** The fundus photographs, fundus autofluorescence (FAF) images, and optical coherence
37 tomographic (OCT) images indicated severe retinal degeneration involving the macula even at a
38 young age (20s) in all the patients. The areas of surviving photoreceptor in the central macula were
39 seen as hyper-autofluorescent regions in the FAF images and preserved outer retinal structure in the
40 OCT images, and they were identifiable in the AO fundus images in 8 eyes. The borders of the
41 surviving photoreceptor areas were surrounded by hyporeflective clumps, presumably containing
42 melanin, and the size of these areas decreased progressively during the 4-year follow-up period. The
43 disappearance of the surviving photoreceptor areas was associated with complete blindness.

44 **Conclusion:** Patients with RP associated with the m1 variant have a progressive and severe retinal

45 degeneration that begins at an early age. Monitoring the surviving photoreceptor areas by AO fundus

46 imaging can provide a more precise pathological progress of the retinal degeneration.

52

53 **Introduction**

54 Retinitis pigmentosa (RP) represents a heterogeneous group of retinal disorders that is characterized
55 by a progressive degeneration of both the rod and cone photoreceptors bilaterally. The *RPI* gene was
56 the first gene identified to cause autosomal dominant RP (adRP) [1, 2], and it was later found to also
57 cause autosomal recessive RP (arRP) [3-6]. Recently, *RPI* was reported to be associated with
58 autosomal recessive macular dystrophy and autosomal recessive cone-rod dystrophy [7, 8]. *RPI*
59 encodes a multimodular protein of 2156 amino acids, and it is a member of the doublecortin family.
60 *RPI* is present in the ciliary axoneme of both rods and cones [9]. Mutations in *RPI* is associated
61 with a decrease in the best-corrected visual acuity (BCVA) which is due to a ciliopathic phenotype
62 caused by an abnormal stacking of the outer segment discs of rods and cones [10].

63 To date, at least 170 mutations have been reported in *RPI*, and most of these mutations cluster
64 within its last exon, exon 4, cumulatively accounting for approximately for 5.5% of all adRP and
65 up to 4.5% of all autosomal arRP cases [5, 11].

66 Our earlier study by whole-genome sequence screening of Japanese patients identified a new,
67 unusual mutation consisting of an insertion of a mobile *Alu* element in exon 4 of the *RPI* gene
68 (c.4052_4053ins328/p.Tyr1352Alafs*9 ; m1) [12]. This m1 insertion variant causes a disruption of
69 the reading frame by introducing 328 additional nucleotides and a premature termination codon in
70 the canonical *RPI* coding sequence. Additional targeted screening for the m1 variant in 330

71 Japanese patients identified 15 other Japanese individuals who carried this variant [12]. These
72 findings indicated that m1 is a relatively frequent cause of retinal degeneration in the Japanese RP
73 patients. However, precise phenotypic analyses were not performed in these earlier studies. Thus,
74 the purpose of this study was to determine the pattern of progression of the retinal degeneration in
75 arRP patients with the m1 variant of the *RPI* gene using adaptive optics (AO) fundus imaging.

76

77 **Methods**

78 This was an observational case series conducted at Nagoya University Hospital. The study protocol
79 adhered to the tenets of the Declaration of Helsinki and was approved by the Institutional Review
80 Board of Nagoya University (approval number: 2010-1067). A written informed consent was
81 obtained from all participants. We studied 9 patients from 5 unrelated families in whom the m1
82 mutation had been identified.

83

84 **Genetic analyses.** In all families, genomic DNA was extracted from peripheral lymphocytes
85 according to standard procedures. The genetic data of patients NA0039, NA1039, NA0070, NA0201,
86 NA1201, and NA0209 were obtained earlier by whole genome sequencing and direct sequencing
87 [12]. The m1 and another frameshift variant (c.4196delG/p.Cys1399Leufs*5, m2) in patients
88 NA1048 and NA1201 and some of the unaffected family members were analyzed in this study. A

89 pair of primers was designed to screen for the presence of the m1 and m2 variants in exon 4 of the
90 *RPI* gene; forward: 5'- AGGCTTGTTTCCTAGGAGAGGT-3', reverse: 5'-
91 TTCTGCTTCTTTTTCACTTAGGC-3'. The presence of m1 variant was confirmed from the
92 differences in the size of the polymerase chain reaction (PCR) product by electrophoresis. The PCR
93 products were purified and both strands of the gene were sequenced with an automated sequencer
94 (Fasmaq, Atsugi, Kanagawa, Japan).

95

96 **Clinical Evaluations.** Clinical data were obtained from the medical records. All patients had visual
97 acuity measurements, Goldmann perimetry, conventional fundus photographs, and spectral-domain
98 optical coherence tomography (SD-OCT, Spectralis; Heidelberg Engineering, Heidelberg, Germany).
99 Fundus autofluorescence (FAF) imaging was performed with an ultra-widefield imaging device
100 (Optos P200Tx; Optos, Dunfermline, UK) in 8 patients.

101 Fundus images with microscopic resolution were obtained using the flood-illuminated AO retinal
102 camera (rtx1, Imagine Eyes, Orsay, France). This system was used in an earlier investigations to
103 obtain images of individual cone photoreceptors [13-16]. Montage images were constructed within
104 6° of the fovea using the i2k Retina software (DualAlign LLC, Clifton Park, NY, USA). The
105 densities of the cone photoreceptors in NA0209 and one normal control eye were automatically
106 calculated using a software (AO detect v0.1, Imagine Eyes, France) and subsequently corrected

107 manually as described[13, 15, 16]. The area of analysis was 80×80 pixels or approximately 65
108 $\mu\text{m} \times 65 \mu\text{m}$ at 1° and 3° from the fovea on the nasal side and 3° from the fovea on the temporal
109 side. To measure the size of surviving photoreceptor area, the processed images were analyzed with
110 the ImageJ software (version 1.48; the National Institutes of Health, Bethesda, MD, USA). The
111 axial length (AL) was obtained by the IOL Master (Carl Zeiss Meditec, Dublin, CA), and the AL
112 was used to adjust for the different degrees of magnification caused by differences in the AL.
113 The decimal BCVA was converted to the logarithm of the minimum angle of resolution (logMAR)
114 units for the statistical analyses. Counting fingers (CF), hand motion (HM), light perception (LP),
115 and no light perception, were designated as 1.85, 2.30, 2.80, and 2.90 logMAR units, respectively.

116

117 **Results**

118 Nine affected patients from 5 families with a clinical diagnosis of RP and harboring m1 variants
119 were studied. Five patients from 3 families had the m1 variant homozygously and 4 patients from 2
120 families had the m1 variant compound heterozygously with another frameshift variant
121 (c.4196delG/p.Cys1399Leufs*5, m2). The pedigrees of the 5 families are presented in Figure 1. All
122 five families were originally from Japan, and any mixture with other ethnicities was not reported.
123 Autosomal recessive family history was reported in 4 families and sporadic case was reported in one

124 family (Family #3). The parents of the patients were not affected even though they have the m1 or
125 m2 variant heterozygously.

126 The demographics of the clinical characteristics are presented in Table. The mean age was $17.9 \pm$
127 6.2 years with a range of 8 to 27 years at the initial examination and that was 30.4 ± 6.5 years with
128 a range of 19 to 39 years at the last examination. The mean and median observation period was
129 12.2 years and 13 years respectively. The initial symptom of all patients was night blindness and 8
130 patients experienced it from their childhood, while one patient (NA0209) first noted the night
131 blindness at age 15 years.

132 **Visual acuity.**

133 Even at the initial visit, the BCVA was worse than 1.0 (decimal visual acuity) in 8 of the patients.
134 BCVA was worse than 0.3 in the better eye in 5 patients at the last examination. The visual fields
135 were severely constricted even at a young age, and most of the patients had paracentral scotomata
136 with peripheral constriction or a central island. Electroretinograms (ERGs) were barely
137 recordable in 2 patients and non-recordable in the remaining 6 patients (ERG data of NA1039 was
138 unavailable.). These findings indicated panretinal degeneration in all of the patients.

139 The course of the decrease in the BCVA of each patient is shown in Figure 2. Due to the early
140 involvement of the macula, the BCVA had decreased to worse than 0.1 (decimal), which is 1.0
141 logMAR units, in at least one eye by the thirties. The BCVA tended to decrease gradually after

142 initial visit. Then the BCVA deteriorated to worse than 0.1 (decimal) within a relatively short time
143 in patients NA0039, NA0201, NA1209, and NA1201 (Fig. 2).

144

145 **Fundus images.**

146 Fundus photographs were obtained from all 9 patients (Fig. 3), and ultra-widefield FAF images

147 were obtained from 8 patients (Fig. 4). All patients except NA0209 had severe degeneration

148 accompanied by bone-spicule pigmentation around the arcade vessels and macular degeneration.

149 FAF showed patchy and coalescent hypo-autofluorescent areas at the posterior pole which

150 indicated atrophy of the retinal pigment epithelium (RPE). Fine hypo-autofluorescent patchy areas

151 were present in the peripheral retina in all cases except NA0209. The fundus and FAF of case

152 NA0209 appeared to be a much milder phenotype compared to those of the other patients; fundus

153 showed minimum macular abnormalities, FAF showed hyperreflectivity in macular area, and small

154 patchy hypo-autofluorescence at the fovea (Figure 5).

155 OCT images of all the cases are shown in Figure 6. The OCT images showed abnormalities in the

156 outer retina, e.g., disrupted ellipsoid zone (EZ) and thinning of the outer nuclear layer. The EZ was

157 totally absent in all cases, except case NA0209, and several fine hyperreflective structures, like

158 tubulations, were found on the RPE in most of the eyes as shown by yellow arrows in Figure 6.

159

160 **Progression of retinal degeneration in case NA0209.**

161 The clinical manifestations of case NA0209 were much milder than those of the other patients; the
162 patient had no bone-spicule pigmentation, fewer hypo-autofluorescent patchy areas, and relatively
163 preserved BCVA. The changes of the FAF and OCT images of case NA0209 during a 5-year
164 follow-up period are shown in Figure 5. FAF showed an increase in the number of fine
165 hypo-autofluorescent patchy spots around the arcade vessels and the fovea. Similar features were
166 found in the eyes of his sister (case NA1209 in Fig. 4). In addition, OCT showed a severe reduction
167 of retinal thickness with the central retinal thickness reduced from 163 μm to 131 μm . These results
168 indicated a progressive retinal degeneration both in the macular and peripheral retina. The AO
169 fundus images at 21-years-of-age showed cone mosaics although they were sparsely distributed
170 compared to those of normal control eyes (Fig. 5B). The cone densities at the 1° and 3° from the
171 fovea on the nasal side were 11231/mm² and 7718/mm² respectively, and that at 3° on the temporal
172 side was 8984/mm². As reference, the of cone densities in a normal control eye at 1° and 3° from the
173 fovea on the nasal side and 3° on the temporal side were 31042/mm², 23283/mm², and 24333/mm²,
174 respectively.

175

176 **Analyses of AO fundus images of surviving photoreceptor areas.**

177 We obtained the AO fundus images of 8 patients except case NA1039. The images of one case
178 (NA0048) were difficult to analyze because the quality was poor due to unsteady fixation. In general,
179 AO fundus imaging has been used to detect and count the number of photoreceptors in eyes with
180 hereditary retinal disorders. However, cone mosaics were detected in the AO images only in the eyes
181 of case NA0209 (Fig. 5). Therefore, we focused on other retinal structures in the AO images.

182 The changes of AO images of the right eye of case NA0201 during a 4-year follow-up period are
183 shown in Figure 7. Isolated, small, and deeply-colored areas were detected in the fundus
184 photographs corresponding to the areas of the hyper-autofluorescence in the FAF images of the
185 central macula. The remaining hyperreflective structures on the RPE in OCT images corresponded
186 to the hyper-autofluorescent areas in the FAF images. The AO fundus images precisely identified
187 the areas of hyper-autofluorescence in the FAF images, which presumably represented island-like
188 residual photoreceptor areas and named “photoreceptor islands”. In contrast to their surrounding
189 surfaces, the areas were homogenous even though the cone mosaics were invisible. The edges of
190 the islands were partially covered by hyporefective clumps (HRCs). HRCs were observed not only
191 at the border of the islands but also around the photoreceptor islands. Higher magnified images
192 showed that the small HRCs participated in the formation of the larger HRCs (Fig. 7 top right). The
193 size of photoreceptor island appeared smaller and less homogenous after 4 years which made their
194 borders unclear. The mean area of the residual photoreceptor island measured in AO fundus images

195 was reduced from $6.0 \times 10^5 \mu\text{m}^2$ in 2013 to $4.3 \times 10^5 \mu\text{m}^2$ in 2015, and to $2.9 \times 10^5 \mu\text{m}^2$ in 2017.

196 The BCVA decreased from 0.13 (decimal) in 2013 to 0.06 in 2015, and 0.02 in 2017. The

197 corresponding areas of the OCT images showed a decrease in retinal thickness due to a reduction of

198 the thickness of the outer nuclear layer (ONL, Fig. 7).

199 Similar AO findings were found in other 7 eyes; the right eye (Rt) and left eye (Lt) of NA1048,

200 NA0201Lt, NA1201Lt, NA0039Lt, NA0070Rt, and NA1209Lt. However, the quality of the AO

201 images of NA201Lt (BCVA; 0.1) and 1209Lt (BCVA; 0.02) were poor, and the borders of the

202 photoreceptor islands were too indistinct to analyze. In 5 eyes (NA0039Rt, NA1201Rt, NA0070Lt,

203 NA1209Rt, and NA1209Rt eyes) the photoreceptor islands could not be detected in the FAF or in

204 the AO images presumably due to a complete loss of the residual photoreceptor areas. The BCVA in

205 these eyes was close to total blindness and ranged from LP to 0.05 (decimal). In addition to the AO

206 image of NA0201Rt, those of NA1201Lt, NA0039Lt, and NA0070Rt eyes were followed for about

207 four years, and the baseline images are shown in Figure 8. The OCT images showed that the fine

208 structures appeared like outer retinal tubulations on the RPE in the corresponding areas. The course

209 of the reduction in the size of the photoreceptor islands measured in AO fundus images and BCVA

210 in NA0039Lt, NA0201Rt, NA1201Lt, and NA0070Rt are shown in Figure 8B. During the 4 year of

211 follow-up period, the size of the photoreceptor island in case NA1201Lt was reduced from $8.2 \times$

212 $10^5 \mu\text{m}^2$ to $4.8 \times 10^5 \mu\text{m}^2$, however the BCVA was maintained at 0.5 (decimal). On the other hand,

213 the size of photoreceptor islands in the other 3 eyes (NA0039Lt, NA0201Rt, and NA0070Rt)
214 decreased to less than $3.0 \times 10^5 \mu\text{m}^2$ with a reduction of the BCVA to <0.1 (decimal). The AO
215 images of NA1048Rt and Lt were obtained only once and the sizes were $12.1 \times 10^5 \mu\text{m}^2$ and $25.1 \times$
216 $10^5 \mu\text{m}^2$ respectively (images not shown) with relatively preserved BCVA (0.5 in both eyes).

217

218 **Discussions**

219 Several *RP1* variants have been reported to cause adRP or arRP in Japanese patients [6, 7, 17-19].

220 The m1 variant had not been identified as a causative variant of arRP in a large Japanese RP cohort

221 study using targeted resequencing [18,19], although the m1 variant was present in 4.5% of RP

222 patients in our recent study [12]. The reason for this discrepancy might be that the m1 variant was

223 missed by targeted resequencing because the insertion of 328 nucleotides was too large to be

224 detected. Indeed, the m1 variant was first detected by Whole-Genome Sequence screening [12], and

225 our earlier targeted resequencing could not detect the m1 variant in case NA0201 although the m2

226 variant was detected [19]. This indicated that the m1 variant might be the cause of patients whose

227 causative genes had not been identified by targeted resequencing, especially in early onset and

228 severe RP cases with macular involvement.

229 Patients with the m1/m1 and m1/m2 variants appeared to have no significant differences in the

230 course of retinal degeneration; both genotypes shared phenotypic characteristics including severe

231 retinal degeneration with early macular involvement. In addition, clinical courses of our patients
232 resemble that of ARRP caused by other frameshift variants in *RPI*. Thus we speculate the disease
233 mechanism of m1 and m2 is the complete loss of function due to nonsense-mediated mRNA decay.

234 The early BCVA loss was caused by macular degeneration at a younger age which can be explained
235 by the expression of the protein encoded by *RPI* in the ciliary axoneme of both rods and cones [9,
236 10].

237 Our results indicated that all of our patients, except case NA0209, had an early onset of impaired
238 vision that occurred during the first decade of life. This was followed by a severe decrease of the
239 BCVA in the second and third decade which has been reported as a phenotype of arRP caused by
240 *RPI* variants [4, 6, 7, 11, 20]. Only case NA0209 had a relatively late onset retinal degeneration
241 compared to the other patients including his sibling. However, even in this patient, OCT showed a
242 progressive reduction of the retinal thickness and FAF showed a similar retinal degeneration pattern
243 as his sister. In addition, fundus AO images indicated that the cone density was reduced to one-third
244 of that of a normal control at 21-years-of-age. Therefore, his clinical findings might show the early
245 phase of severe retinal degeneration. The reason for the differences of the progression between the
246 two siblings was not determined but some other genetic factors rather than environmental factors
247 might be responsible for this because these siblings had been raised in a similar environment.

248 The FAF images are produced by retinoid byproducts of the visual cycle that accumulate in the
249 RPE [21], and they are assumed to be related to the remaining functional retina in eyes with
250 inherited retinal diseases [22, 23]. In the late stages of choroideremia, some patients have areas of
251 residual hyper-autofluorescence, called scalloped regions, surrounded by hypo-autofluorescent
252 areas [22, 23]. These hyper-autofluorescent areas are reported to be correlated with the areas of
253 surviving photoreceptors determined from multiple slices through the EZ in the OCT images [22,
254 23]. The size of these residual autofluorescent areas shrinks every year[24], and they have been
255 used to monitor the effectiveness of gene therapy in these types of patients [25]. Similar
256 autofluorescent areas were found in some eyes in our cohort. The high resolution AO fundus
257 images have allowed researchers to detect the subtle changes of the macular structures during the
258 course of retinal degeneration. Therefore, for the evaluation of the photoreceptor structure in
259 “scalloped regions” of choroideremia, our AO image analysis might be useful.

260 Our results showed that the course of reduction of the BCVA was composed of three phases. Most
261 patients had a reduction in the BCVA soon after the initial visit due to an involvement of the
262 macular area. This might be caused by the reduction of cone mosaics as observed in the AO images
263 of case NA209. However, the BCVA was relatively well preserved until the mid-20s, and then the
264 BCVA decreased in a relatively quickly (Fig. 2). The AO image analyses suggested that the
265 preserved photoreceptor islands were responsible for the maintained BCVA of >0.1(decimal). The

266 disruption of the photoreceptor islands appeared to lead to a further decrease in BCVA to nearly
267 complete blindness. Indeed, the FAF and AO images did not detect any photoreceptor islands in
268 near blind eyes such as the NA0039Rt, NA1201Rt, and NA1209Rt and Lt.

269 The relationships between the AO images and pathological changes of the retina have not been
270 accurately determined mainly because of the limited number of studies of the high-resolution AO
271 images. HRCs were found at the edge of photoreceptor islands but their origins are uncertain.
272 Because melanin is the ocular pigment with the highest absorption in flood illumination near
273 infrared AO imaging, it is possible that the HRCs are composed of melanin molecules and/or their
274 derivatives. Some of the round HRCs observed *in vivo* in the degenerating retina with geographic
275 atrophy were shown to be of similar in size and shape to ectopic RPE cells reported by histology
276 [26]. If this is true, the detached RPE cells might migrate to the edge of the photoreceptor islands
277 because the appearance and size of the HRCs in our study (Fig. 7) are identical to those in the
278 previous report [26]. It is known that following the death of all photoreceptors, the RPE cells
279 detach from Bruch's membrane and migrate to perivascular sites in the inner retina producing the
280 bone spicule pigments [27]. It is possible that a similar migration of RPE is related to the loss of
281 photoreceptor islands.

282 Our retrospective study has several limitations. The AO fundus images were analyzed from only 7
283 eyes because of difficulties in recording high quality images from eyes with poor fixation. In

284 addition, statistical analyses could not be performed due to the low number of images and different
285 times of obtaining the images. In addition, not only the size but also the quality of photoreceptor
286 island images would affect the BCVA because the BCVA of NA1201Lt was maintained at 0.5 in
287 spite of a decrease in the size of photoreceptor islands. Future investigations of the size and quality
288 of the photoreceptor islands using microperimetry might provide additional information that will
289 help in making a prognosis of RP patients.

290 Another limitation is "photoreceptor island" is not a common feature of the RP. Usually in the
291 advanced stage of RP, AO images can detect only mottled structures with unknown origin and
292 "photoreceptor island" were found in a small portion of the eyes with RP. Thus our AO image
293 analysis can be applied for the limited number of RP patients.

294 In conclusion, we have analyzed the phenotypic characteristics of arRP eyes carrying the m1
295 variant. These patients had severe retinal degeneration with early macular involvement as reported
296 in arRP eyes caused by other RPI variants [4, 6, 7, 11, 20]. In the course of macular degeneration
297 in our cohort, the AO images showed not only the reduction of the cone intensity in one patient but
298 also showed the process of the reduction of the residual photoreceptor areas at the end stage of RP.
299 These changes indicated that total blindness appeared to be related to the loss of the photoreceptor
300 islands. Monitoring the fine retinal structures and the cone mosaics by AO fundus imaging could

301 provide further prognostic implications and can be used for the evaluation of new therapeutic

302 applications.

5	NA0209	M	15	20	1	1	Paracentral scotoma	Reduced	26	0.8	0.6	m1	m2	Cone mosaic	Cone mosaic
5	NA1209	F	6	19	0.4	0.7	Paracentral scotoma, peripheral constriction	ND	30	HM	0.02	m1	m2	No photoreceptor island	Photoreceptor island

ARRP=autosomal recessive retinitis pigmentosa. BCVA= best corrected visual acuity. F=female; HM=hand motion; LE=left eye; LP=light perception; M=male; NA=not available; ND=not detectable; No.=number; RE=right eye; m1=c.4052_4053ins328/p.Tyr1352A1afs*9 (Alu insertion); m2=c.4196del(G/p.Cys1399Leufs*5

387 **Figure Legends**

388 **Figure 1. Pedigree charts of 9 autosomal recessive retinitis pigmentosa cases carrying the m1**
389 **variant (c.4052_4053ins328/p.Tyr1352Alafs*9) in the *RPI* gene.**

390 The m2 variant (c.4196delG/p.Cys1399Leufs*5) was found in 2 families. There was no reported
391 consanguinity in any of these pedigrees. Probands are shown by the arrows.

392

393 **Figure 2. Graph showing the course of the best-corrected visual acuity over time in all eyes**
394 **from our cohort.**

395 Snellen visual acuity was converted to the logarithm of the minimum angle of resolution
396 (logMAR). R; right L; left

397

398 **Figure 3. Fundus color photographs of the right eye of the 9 patients from 5 families (1-5)**
399 **with autosomal recessive retinitis pigmentosa caused by a variant of the *RPI* gene;**
400 **c.4052_4053ins328/p.Tyr1352Alafs*9 (m1).**

401 The age of the patients at which the photograph was taken is shown. All the patients except NA0209
402 had severe panretinal degeneration including macula. Y.O. ; year old .

403

404 **Figure 4. Fundus autofluorescence (FAF) images of the right eye of 8 patients from 5 families**

405 **(1-5).**

406 The age of the patients at which the photograph was taken is shown. All patients except NA0209 had

407 patchy and coalescent hypo-autofluorescent areas including macula. Y.O. ; year old .

408

409 **Figure 5. Multimodal images in case NA0209.**

410 a. Changes of retinal images during the follow-up period. Fundus autofluorescence (FAF, upper)

411 shows fine hypo-autofluorescent patchy spots around the arcade vessels and at the fovea appeared

412 during 5 years. The OCT images show a marked reduction of the retinal thickness in 5 years. Arrows

413 indicate the residual EZ at 20-years-of-age which disappeared in 5 years. The scale bar is 200 μm .

414 b. Adaptive optics (AO) fundus images of case NA0209 at 21-years-of-age. A montage image is

415 shown on the left. Magnified images of the white square (at 3 degrees from the central fovea on the

416 temporal side and 1 and 3 degrees on the nasal side; shown as T3, N1 and N3 respectively) in the

417 montage image are shown. For comparison the AO images of a normal control at 3 degrees from

418 the central fovea on the temporal side is shown (N3 Normal). The scale bar is 20 μm in the

419 magnified AO images as well.

420

421 **Figure 6. Optical coherence tomographic (OCT) images of the right eye of the 9 patients from 5**
422 **families (1-5). The OCT images shows thinning of the retina and abnormalities in the outer retina in**
423 **all cases. Several fine hyperreflective structures can be seen on the RPE shown by the yellow**
424 **arrows.**

425

426 **Figure 7. Progressive reduction of surviving photoreceptor areas (photoreceptor islands) in the**
427 **right eye of case NA0201.**

428 Fundus photograph (top left) shows a deep colored area in the central macula which was detected as
429 a hyper autofluorescence area in fundus autofluorescence (FAF, top middle) images. The white
430 squares in the color fundus photograph and FAF area corresponds to fundus AO images below.

431 Successive AO images were recorded on June 2013, January 2015, and January 2017. The OCT
432 images obtained on the same days are shown on the right of each AO fundus image, and the scanned
433 area is shown by the dotted arrows in the AO fundus images. Illustrative images of the photoreceptor
434 islands are shown at the bottom left of each AO image. The size of photoreceptor islands decreases
435 progressively. The magnified image of the white square in the AO fundus image on June 2013 is
436 shown at the top right. The edge of the photoreceptor island is partially covered by hyporefective
437 clumps (HRCs). Small HRCs participate to form the large clumps. HRCs surrounding the

438 photoreceptor island are shown in arrows and HRCs seen around the photoreceptor island are shown
439 in arrow heads.

440

441 **Figure 8. Findings of NA1201 left, NA0039 left, and NA0070 right eyes**

442 a. Multimodal images of photoreceptor islands. The color fundus photograph (top left) and fundus
443 autofluorescence (FAF; top right), AO fundus image, and OCT image of each eye are shown. The
444 area surrounded by the white line in the color fundus and FAF images correspond to the montage of
445 the AO fundus images (middle). The first recorded AO fundus images of each patient (baseline of
446 analysis) and OCT images (below) on the same day are shown. The scanned areas for the OCT
447 images are shown by the yellow dotted arrows in the AO fundus images. The fundus and FAF
448 images obtained on the closest day to the AO images are shown. Illustrations of the photoreceptor
449 islands are shown at the upper left of each AO fundus image. Hyper autofluorescence areas in the
450 central macula detected in FAF are clearly visible in the AO fundus images.

451 b. Reduction in the size of the photoreceptor islands in four eyes (three eyes from A and 1 eye from
452 Figure 4). The size of the photoreceptor island gradually decrease. The visual acuity (decimal) at
453 each time point is also shown.
